### Abstract

The hydraulic design and analysis of flow conditions in pipe networks are dependent upon estimating the friction factor,  $f$ . The performance of its explicit formulations and those of artificial intelligence (AI) techniques are studied in this paper. The AI techniques used here include artificial neural networks (ANNs) and genetic programming (GP); both use the same data generated numerically by systematically changing the values of Reynolds numbers,  $Re$ , and relative roughness,  $\varepsilon/D$ , and solving the Colebrook-White equation for the value of  $f$  by using the successive substitution method. The tests included the transformation of  $Re$  and  $\varepsilon/D$  using a logarithmic scale. This study shows that some of the explicit formulations for friction factor induce undue errors, but a number of them have good accuracy. The ANN formulation for the solving of the friction factor in the Colebrook-White equation is less successful than that by GP. The implementation of GP offers another explicit formulation for the friction factor; the performance of GP in terms of  $R^2$  (0.997) and the root-mean-square error (0.013) is good, but its numerically obtained values are slightly perturbed.

**Key Words:** Pipe friction factor, Darcy-Weisbach equation, implicit/explicit equations, artificial neural network, genetic programming

### 1. Introduction

The understanding of flow equations in closed conduits reached its maturity in the early 20th century, whereby flows in such systems are driven by pressure differences between 2 different locations and the equation is referred to as the Darcy-Weisbach equation. This hydraulic equation serves as the basis for hydraulic design and analysis of water distribution systems, and it is expressed in terms of pressure drop, which is a directly measurable quantity of friction. However, the mathematical formulation of the problem includes an empirical friction parameter,  $f$ , for which the Colebrook-White equation is one well-known implicit formulation, such that the factor appears on both sides of the equation. This implicit problem is not intractable, as it can be

---

\*Corresponding author

treated by iterative techniques, although it is cumbersome. Until the wide application of artificial intelligence (AI) in the 1990s, the challenge was to develop its explicit formulations, but, since then, the application of AI techniques is also a focus of research.

The Colebrook-White equation integrates important theoretical work by von Karman and Prandtl by accounting for both smooth and turbulent flow regimes in terms of 2 parameters, the Reynolds number,  $R_e$ , and the relative roughness as a measure of friction,  $\varepsilon/D$ . Alternative methods of solving the Colebrook-White equation include iterative methods, analytical solutions using the Lambert  $W$  function, use of an explicit equation, soft computing techniques that recognize that  $f$ -values are not precise, and a host of AI techniques used in recent years, including the artificial neural network (ANN) technique and genetic programming (GP). However, ANNs and GP assume that  $f$ -values are precise.

ANNs are parallel information processing systems that emulate the working processes in the brain. A neural network consists of a set of neurons or nodes arranged in layers; in the case that weighted inputs are used, these nodes provide suitable inputs by conversion functions (Kışı, 2005). Each neuron in a layer is connected to all of the neurons of the next layer, but without any interconnection among neurons in the same layer. Applications of ANNs to hydraulics go back to the 1990s and remain in active use today.

The GP methods, first proposed by Koza (1992), are wide-ranging and similar to genetic algorithms (Goldberg, 1989). GP techniques are robust applications of optimization algorithms and represent one way of mimicking natural selection. These techniques derive a set of mathematical expressions to describe the relationship between the independent and dependent variables using such operators as mutation, recombination (or crossover), and evolution. These are operated in a population evolving over generations through a definition of fitness and selection criteria. Applications of GP suit a wide range of problems and are particularly applicable to cases in which the interrelationships among the relevant variables are poorly understood or suspected to be wrong, or conventional mathematical analyses are constrained by restrictive assumptions but approximate solutions are acceptable (Banzhaf et al., 1998).

In smooth pipes, friction factor  $f$  depends only on  $R_e$ , and Gulyani (1999) provided a revision and discussion of the correlations more commonly used to estimate its value. However, the focus of recent research is largely on the full Colebrook-White equation.

More (2006) applied an analytical solution for the Colebrook-White equation for the friction factor using the Lambert  $W$  function. A close match was then observed by comparing the friction factor obtained from the Colebrook-White equation (used iteratively) and that obtained from the Lambert  $W$  function. Fadare and Ofidhe (2009) studied the ANN technique for the estimation of the friction factor in pipe flows and reported a high correlation factor of 0.999.

Yang et al. (2003) used ANNs to predict phase transport characteristics in high-pressure, 2-phase turbulent bubbly flows. Their investigation aimed to demonstrate the successful use of neural networks in the real-time determination of 2-phase flow properties at elevated pressures. They established 3 back-propagation neural networks, trained with the simulation results of a comprehensive theoretical model, to predict the transport characteristics (specifically the distributions of void-fraction and axial liquid-gas velocities) of upward turbulent bubbly pipe flows at pressures in the range of 3.5-7.0 MPa. Comparisons of the predictions with the test target vectors indicated that the root-mean-square error (RMSE) for each of the 3 back-propagation neural networks was within 5% to 6%.

To date, the application of GP in hydraulic engineering has been limited. Davidson et al. (1999)

determined empirical relationships for the friction in turbulent pipe flows and the additional resistance to flow induced by flexible vegetation, respectively. Giustolisi (2004) determined the Chezy resistance coefficient in corrugated channels. The authors are not aware of the application of GP to the Colebrook-White equation.

This paper is focused on treating the friction factor as having a precise value, but, in reality, this parameter is variable over time and data are often insufficient, ambiguous, and/or uncertain for precise treatments. Therefore, Yıldırım and Özger (2009), Yıldırım (2009), and Özger and Yıldırım (2009) investigated this parameter with soft computing techniques using various formulations of the friction factor, allowing them to identify precise values of friction values using neuro-fuzzy techniques.

The overall objective of the present study was to evaluate the performances of explicit formulations for estimating the friction factor,  $f$ , in the Darcy-Weisbach equation, while using ANNs and GP to avoid the need for a time-consuming and iterative solution of the Colebrook-White equation. The study involves the generation of data and comparisons between the various techniques with the numerical solutions of the Colebrook-White equation.

## 2. Models and methodology

### 2.1. Flow equation

The energy loss due to friction in Newtonian liquids flowing in a pipe is usually calculated with the Darcy-Weisbach equation, as follows.

$$h_f = f \frac{L}{D} \frac{V^2}{2g} \quad (1)$$

In this equation,  $f$  is referred to as the Moody or Darcy friction factor. This may be reformulated as follows.

$$f = \frac{D}{L} \frac{g h_f}{1/2 V^2} = \frac{D}{L} \frac{\Delta P}{1/2 \rho V^2} \quad (2)$$

The friction factor depends on the Reynolds number,  $Re$ , and on the relative roughness of the pipe,  $\varepsilon/D$ .

For both smooth and turbulent flows, the friction factor is estimated with the following equation, developed by Colebrook and White (1937).

$$\frac{1}{\sqrt{f}} = -2 \log \left( \frac{\varepsilon}{3.7D} + \frac{2.523}{Re \sqrt{f}} \right) \quad (3)$$

### 2.2. Explicit formulations

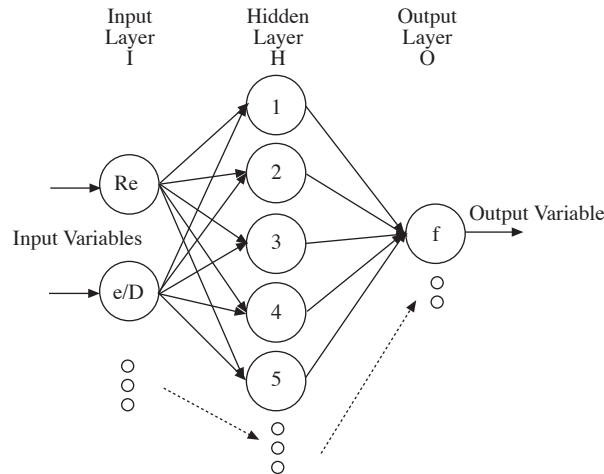

The Colebrook-White equation is valid for  $Re$  values ranging from 2000 to  $10^8$ , and for values of relative roughness ranging from 0.0 to 0.05. The formula is often used in pipe network simulations. Its form is notably implicit, as the value of  $f$  appears on both sides of the equation, and its accurate solution is often very time-consuming, requiring many iterations. An approximate equation for  $f$  that does not require iteration can be used to improve the speed of simulation software. This was a subject of active research in the past, leading to a range of explicit formulations that are summarized in Appendix I. A study of the performance of these explicit equations was one of the aims of this paper.

### 2.3. Data specification and implementations of the AI models

The data in this modeling study were generated using a numerical procedure based on Eq. (3). The data generation included a systematic variation of  $R_e$  ranging from 2000 to  $10^8$  (using 74 values of  $R_e$ ) and the varying of  $\varepsilon/D$ , ranging from  $10^{-6}$  to 0.05 (28 values). Different combinations of  $R_e$  and  $\varepsilon/D$  serve for the generation of data points in terms of  $f$ , where the  $f$ -value for each set of data is calculated by the numerical solution of the Colebrook-White equation using the successive substitution method. The dataset consisted of a total of 2072 points. Input variables were  $\varepsilon/D$  and  $R_e$ , and the output was  $f$ . A selection of the generated data is shown in Appendix II and Table II.1.

### 2.4. Artificial neural networks

Any layer consists of predesignated neurons, and each neural network includes one or more of these interconnected layers. Figure 1 shows a 3-layered structure that consists of 1 input layer, I; 1 hidden layer, H; and 1 output layer, O. All of the neurons within a layer act synchronously. The operation process of these networks is such that the input layer accepts the data and the intermediate layers processes them, and, finally, the output layer displays the resulting outputs of the model application. During the modeling stage, the coefficients related to the present errors in the nodes are corrected by comparing the model outputs with the recorded input data (Rakhshandehroo et al., 2010).

**Figure 1.** Neuron layout of artificial neural network (ANN).

The data for training the ANN model were generated using the numerical procedure described above. The dataset consisted of a total of 2072 points, of which 70% (1450 data points) were selected for the training process and 30% were selected as test data (622 data points). The optimal ANN configuration was selected from among various ANN configurations based on their predictive performances. The performance of the various ANN configurations was studied with 2 error measures: the determination coefficient,  $R^2$ , and RMSE.

### 2.5. Genetic programming

Implementation of GP models involves a number of preliminary decisions, including the selection of a set of basic operators such as  $\{+, -, *, /, \wedge, \sqrt{\quad}, \log, \exp, \sin, \arcsin, \dots\}$  to construct a function, such as the reconstruction of

an explicit equation for  $f$ , traditionally expressed by Eq. (3). The GP modeling programs provide operators like crossover and mutation to the winners, “children,” or “offspring” to emulate natural selection, in which crossovers are responsible for maintaining identical features from one generation to another but mutations cause random changes. The evolution starts from an initially selected random population of models, where relationship  $f$  between the independent and dependent variables is often referred to as the “model,” the “program,” or the “solution.” The population is allowed to evolve from one generation to another by virtue of a selected fitness criterion, and new models replace the old ones in this evolutionary process by having demonstrably better performance.

The study was carried out using GeneXpro software (Ferreira, 2001a, 2001b), which uses a gene expression method. Although this has differences from GP, both are inspired by natural selection in principle. For more detail on the implementation of GP models, see Ghorbani et al. (2010).

In this study, 4 basic arithmetic operators (+, -,  $\times$ , /) and some basic mathematical functions ( $\sqrt{\quad}$ , log, and  $e^x$ ) were used. Like with ANNs, input variables were  $\varepsilon/D$  and  $R_e$ , and the output was  $f$ . A large number of generations (5000) were tested. The performance of GP was studied with 3 error measures:  $R^2$ , RMSE, and relative error (RE), as defined in Section 2.6.

## 2.6. Performance measures

The study involved comparisons, for which 3 performance measures were used to highlight different aspects of the problem. These measures were RMSE,  $R^2$  and absolute RE which is defined as follows

$$RE = |f_{True} - f_{Estimated}| / f_{True}$$

Here,  $f_{True}$  is calculated from the Colebrook-White equation by the successive substitution method, and  $f_{Estimated}$  is the output value from the explicit, GP, or ANN models.

## 3. Results

### 3.1. Performances of explicit equations

The performances of explicit equations for the Colebrook-White equations (presented in Appendix I) was investigated by comparing them against the numerical solution of the Colebrook-White equation for  $f$ -values using the data created in this study and presented in Appendix II. The results are presented in Figure 2, and their performances are summarized in Table 1 by categorizing them into 3 sets, those having inadequate, adequate, and good performances, with methods falling into the latter categories being very successful.

### 3.2. Implementation of ANN

The initial identification of the model configurations did not employ any transformation of either data input or output. Its optimum configuration was selected by trial and error, by testing the set shown in Table 2. The identified architecture was 2-5-1 (input layer, 2 neurons; 1 hidden layer, 5 neurons; output layer, 1 neuron), for which the lowest RMSE was 0.0379 and the highest  $R^2$  was 0.977. This led to inadequate predictions of  $f$ -values when the model was implemented in its prediction mode; in particular, unacceptably high errors were obtained for the predicted  $f$ -values corresponding to  $R_e$  values at the lower end of the chosen range. This

indicated that the ANN model was unable to capture the initial curvature in the  $f$ -curves at the specified lower range of  $Re$ .

**Figure 2.** Continued.

Although ANN models do not require any prior knowledge of the relationships among inputs and outputs, a “warm start” is helpful to fine-tune the ANN model. For instance, it is clear from Eq. (3) that the parameter  $f$  is a logarithmic function of both input parameters,  $R_e$  and  $\varepsilon/D$ . For this reason, another set of test runs were carried out to improve the performance of the ANN model by transforming both input data parameters. The  $R_e$  and  $\varepsilon/D$  parameters were transformed using a logarithmic function to the base of 10. The results, shown in Table 3, reveal that the optimum ANN configuration was improved markedly, as its RMSE was reduced to 0.0218 and its  $R^2$  was increased to 0.995.

These results demonstrate the importance of choosing the right transformation of input data parameters and the significant impact that this may have on the overall performance of the ANN model.

### 3.3. Implementation of GP

The GP model was implemented by using the data in Appendix II. The functional setting and default parameters used in the GP modeling during this study are listed in Table 4. The GP model resulted in a highly nonlinear

relationship with high accuracy and relatively low errors. The simplified analytic form of the proposed GP model may be expressed as follows.

**Table 3.** Predicted errors for training and testing dataset of friction factor; different ANN configurations with transformations of input parameters.

Transfer function	No. of hidden layers	No. of neurons/layer	Training		Test	
			RMSE	$R^2$	RMSE	$R^2$

$$f = -0.0575 + \varepsilon/D + e^{-11.764(\varepsilon/D) - \log(2R_n)} + e^{-2.567 + 9.065/R_n - \varepsilon/D} \quad (4)$$

Figure 3 shows the RE in contour-line scheme by using the GP model from Eq. (4). The whole dataset (2072 points) has a mean RE of  $2.52 \times 10^{-5}$ , a maximum RE of 0.000117, and a minimum RE of  $2.64 \times 10^{-12}$ . The contour lines in Figure 3 show that the RE in the GP model is greater only in the upper right part of the graph. This area corresponds to  $\varepsilon/D = 0.03, 0.02, \text{ and } 0.015$ , and  $R_e$  values between  $10^7$  and  $10^9$ . In other areas, the RE for the GP model is low and performs satisfactorily enough for the friction factor estimation. The error statistics of the GP model show that its RMSE and  $R^2$  are 0.013 and 0.997, respectively, compared to the ANN quantitative performance values of RMSE = 0.022 and  $R^2 = 0.995$ . Therefore, the prediction accuracy of the GP model is generally better than that of the ANN model.

#### 4. Discussion of the results

Engineering practices for pipe systems require the calculation of head losses and flows, and a common practice is to embed iterative methods for the calculation of  $f$ -values in the computer programs. However, this study shows that some of the explicit methods perform well and may replace the Colebrook-White equation, particularly in manual calculations, which can rapidly calculate  $f$ -values for given values of  $\varepsilon/D$  and  $R_e$ . The investigations here show a sharp contrast in the performance of the explicit equations when compared with one another, but the accurate ones are attractive.

Figure 3. Contour of relative error for the GP model.

The performance of the ANN model in calculating the friction factor,  $f$ , was investigated by plotting a scatter diagram, as shown in Figure 4. Overall, the results were comparatively acceptable for calculating  $f$ , but the ANN model was less capable than some of the explicit equations, like those used by Chen (1979), Barr (1981), Zigrang and Sylvester (1982), and Romeo et al. (2002).

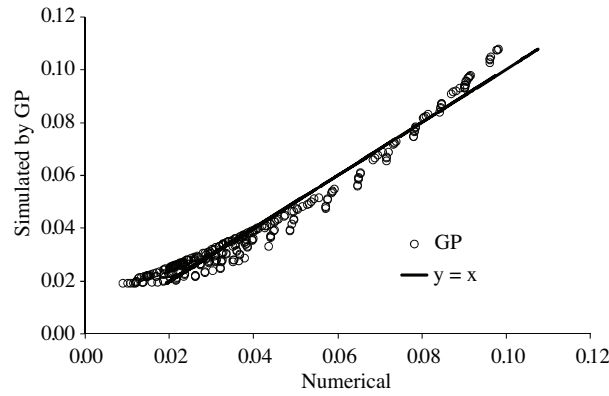

Figure 4. Scatter diagram for performance of ANN and numerical solution of the Colebrook-White equation.

The performance of the GP model in calculating friction factor  $f$  was investigated by plotting a scatter diagram, as shown in Figure 5. Overall, the GP model of the friction factor had some edge over the ANN model, both visually and quantitatively, but, at the same time, the GP model did not perform as well as some of the explicit formulations.

Future work will be directed toward improving the Colebrook-White equation for modern commercial pipes, like spiral and glass-reinforced plastic pipes.

**Figure 5.** Scatter diagram for performance of GP and numerical solution of the Colebrook-White equation.

## 5. Conclusion

The paper focused on different methods used for predicting friction factor  $f$  in the Colebrook-White equation for calculating flows in pipes under pressure; the techniques selected were numerical solutions of the implicit Colebrook-White equations, various explicit forms of the Colebrook-White equation, and 2 applications of AI techniques, namely ANNs and GP techniques. The data were generated systematically for different values of the  $Re$  and  $\varepsilon/D$  parameters using the Colebrook-White equation, and  $f$ -values were obtained using the successive substitution method for the equation's solution.

Preliminary test runs identified optimum ANN and GP models. The ANN model involved a neural network with 1 hidden layer and 5 neurons in that layer. Following the logarithmic transformations of the input data parameters, the trained network was able to perform better, with  $R^2$  and RMSE values of 0.995 and 0.022, respectively (Table 3). The performance of the GP model using the testing data points showed a high generalization capacity, with  $R^2 = 0.997$  and RMSE = 0.013. This model allows for an explicit solution of  $f$  without the need to employ a time-consuming iterative or trial-and-error solution scheme, an approach that is usually associated with the solution of the Colebrook equation in the turbulent flow regime of closed pipes.

Explicit equations remove the need for the iteration required for solving for the friction factor in the Colebrook-White equation, but this study shows that a number of them induce some undue errors. However, this study further identified some of the explicit formulations as accurate. The ANN formulation to solve for the friction factor in the Colebrook-White equation was less successful than the GP approach. Although the performance of GP in terms of  $R^2$  and RMSE was good, its numerically obtained values were slightly perturbed, and the GP model did not perform as well as some of the explicit equations.

## Appendix I

### I.1. Explicit methods

The Colebrook-White equation is a formula often used in pipe network simulation software. Many explicit expressions have been developed to replace it, in which the value of  $f$  appears on both sides of the equation. These explicit formulations are approximations for  $f$  that do not require iteration, and they can hence be used to improve the speed of simulation software.

9	Churchill (1977)	$f = 8 \left( \left( \frac{8}{R_e} \right)^{12} + (A+B)^{-2} \right)^{\frac{1}{12}}$ $A = \left[ -2 \log \left( \left( \frac{\varepsilon/D}{3.7} \right) + \left( \frac{7}{R_e} \right)^{0.9} \right) \right]^{1.6}$ $B = \left( \frac{37530}{R_e} \right)^{1.6}$	(I.8)	Valid for the whole range of $R_e$ (laminar, transition and turbulent)
10	Chen (1979)	$\frac{1}{\sqrt{f}} = -2 \log \left( \frac{\varepsilon/D}{3.7065} - \frac{5.0452}{R_e} \log \left( \frac{(\varepsilon/D)^{1.1098}}{2.8257} + \frac{5.8506}{R_e^{0.8981}} \right) \right)$	(I.9)	Involves 2 iterations of Eq. (3) $4000 < R_e < 4 \times 10^8$ $0.0000005 < \varepsilon/D < 0.05$
11	Barr (1981): analogous to Chen (1979)	$\frac{1}{\sqrt{f}} = -2 \log \left( \frac{\varepsilon/D}{3.7} - \frac{4.518 \log(R_e/7)}{R_e \left( 1 + (R_e^{0.52} (\varepsilon/D)^{0.7}) \right)} \right)$	(I.10)	-
12	Zigrang and Sylvester (1982): similar to chen (1979), but with 3 iterations	$\frac{1}{\sqrt{f}} = -2 \log \left( \frac{\varepsilon/D}{3.7} - \frac{5.02}{R_e} \log \left( \frac{\varepsilon/D}{3.7} - \frac{5.02}{R_e} \log \left( \frac{\varepsilon/D}{3.7} + \frac{13}{R_e} \right) \right) \right)$	(I.11)	-
13	Manadilli (1997): signomial-like equations	$\frac{1}{\sqrt{f}} = -2 \log \left( \frac{\varepsilon/D}{3.70} - \frac{95}{R_e^{0.983}} - \frac{96.82}{R_e} \right)$	(I.12)	$5235 < R_e < 10^8$ , any value of $\varepsilon/D$
14	Romeo et al. (2002)	$\frac{1}{\sqrt{f}} = -2 \log \left( \frac{\varepsilon/D}{3.7065} - \frac{5.0272}{R_e} \log \left( \frac{\varepsilon/D}{3.827} - \frac{4.567}{R_e} \log \left( \left( \frac{\varepsilon/D}{7.7918} \right)^{0.924} + \left( \frac{5.3326}{208.815 + R_e} \right)^{0.945} \right) \right) \right)$	(I.13)	$0 < \varepsilon/D < 0.05$ and $3 \times 10^3 < R_e < 1.5 \times 10^8$

## Appendix II

Generation of data points for numerical study.

Table II.1. Sample of data with combinations of  $\varepsilon/D$ ,  $R_e$ , and  $f$ .
